The increased pathogenesis of the Schistosoma mansoni BH strain compared with the SJ strain has been attributed to the number of granulomas formed in experimental infections, which increase the mortality in definitive hosts. The aim of the present study was to investigate the development of granulomas around the eggs of the S. mansoni BH and SJ strains and to determine whether this host reaction was strain specific. Four experimental groups were analyzed. Two groups contained mice inoculated in the caudal vein with eggs from the S. mansoni BH or SJ strains and the other two contained mice that were infected with cercariae of the BH strain prior to being inoculated with eggs. The number of granulomas per tissue area in the lungs and liver, as well as the size of the granulomas, was analyzed to characterize the response to schistosome infection. The largest granulomatous responses were observed around eggs of the BH strain. Granulomas covered a larger area in the lungs of mice that were previously infected with cercariae and subsequently inoculated with eggs of the BH strain. These results indicated that specific granulomatous responses occurred following an infection with the BH and SJ strains of S. mansoni.

1. Introduction

Schistosomiasis is considered to be the most notable parasitic disease after malaria due to its wide geographic distribution, the large number of people affected by the disease, its severity, and its association with poor sanitary conditions [1, 2].

The primary pathogenic mediators in schistosomiasis are the trematode eggs. A schistosomal granuloma, the characteristic lesion, forms around mature eggs that have been deposited in the tissues of the definitive host. The distribution of eggs in host tissues, the extent of the granulomatous response, and the degree of infectivity of the parasite strain are key factors in the pathogenesis of schistosomiasis [3].

The diverse behavior of different strains of Schistosoma mansoni [4–11] may account for the regional variation observed in clinical schistosomiasis [12]. The degree of morbidity in human schistosomiasis varies regionally, possibly due to variations in parasite infectivity and fecundity [13].

Previous studies have demonstrated a difference in the development of the BH and SJ strains of S. mansoni in the definitive host [4, 6, 7, 14–16]. More hepatic granulomas were observed in mice infected with the S. mansoni BH strain, and a significantly lower percentage of mice survived in this group than in the group of mice that were infected with the SJ strain. In mice, fewer parasites of the BH strain were necessary to obtain equivalent pathogenesis than those with the SJ strain [6]. These experiments demonstrated an increased pathogenicity of the BH strain [6, 10, 17, 18]. In areas that are considered endemic for the BH strain, there are frequent cases of decompensated hepatosplenomegaly, which does not occur in regions where the SJ strain is present. Instead, almost all cases of infection with the SJ strain are asymptomatic, with the exception of rare cases of compensated hepatosplenomegaly [19, 20]. In addition, adult worms and eggs of the BH strain are typically larger than those of the SJ strain [10, 14, 21–27].
A number of factors seem to be fundamentally important for the development of severe forms of schistosomiasis: the number of eggs and the antigens they released; the reinfections; the genetic influence of the host, the hosts immune response to the formation of granulomas, the development of periporal fibrosis and factor modulators, and the associations with aggravating factors such as alcoholism, malnutrition, and hepatitis (particularly hepatitis B and C) which compromise the liver [28]. Mice were experimentally infected and submitted to a low-protein diet using the BH strain of *S. mansoni*. In spite of the reduced number of hepatic granulomas, as well as a reduction in the size of the granuloma, mortality rates among the animals were high [29]. Recent studies [30] used different strains of mice and established an association between malnutrition and the development of hepatic fibrosis. In the state of Minas Gerais (Brazil), the hepatosplenic form of schistosomiasis in children was strongly associated with bathing in streams [31]. In parts of the state of São Paulo (Brazil), characterized by low endemicity, where the main risk factor for *S. mansoni* infection is from leisure in water, there is a significant correlation between the intensity of the infection and the prevalence. The infection rate of the intermediate host B. tenagophila was 0.4% in this case [32]. All of these associated factors indicated that the evolution of mansoni schistosomiasis should be seen as a multidisciplinary phenomenon and individual analysis of each case should be performed to gain a better understanding of the infection.

Considering the importance of *S. mansoni* eggs in the pathogenicity of schistosomiasis and the fact that the induced granulomatous immune response is stage specific [33], the aim of the present study was to investigate the inflammatory response in the lung tissue of mice inoculated in the caudal vein with eggs of the *S. mansoni* BH and SJ strains to determine whether differences existed between the two strains in terms of the inflammatory response around eggs.

### 2. Materials and Methods

The present study received approval from the Animal Experimentation Ethical Committee of the UNICAMP (Comissão de Ética na Experimentação Animal-CEEA-IB-UNICAMP) under protocol number 870-1.

#### 2.1. *S. mansoni* Strains and Egg Collection

Two *S. mansoni* strains were used in the present study: the SJ strain from São José dos Campos (SP, Brazil), which was maintained in populations of sympatric *B. tenagophila* and the BH strain, originally from Belo Horizonte (MG, Brazil), which was maintained in populations of sympatric *B. glabrata*. Cercariae obtained from the snails were used to infect Swiss SPF (specific pathogen free) mice [34]. The mice were exposed to 100 cercariae for two hours. After this time period had elapsed, the cercariae that remained in the test tubes, where the tails of the mice were immersed, were counted.

The eggs from both strains (BH and SJ) of *S. mansoni* were obtained from the intestinal wall of infected mice. Mice were inoculated in the caudal vein with approximately 1000 mature eggs in 0.3 mL of saline solution [35].

#### 2.2. Experimental Groups

Four experimental groups were established in the present study. Group I contained 12 mice inoculated with eggs from the *S. mansoni* BH strain. Group II contained 12 mice inoculated with eggs from the *S. mansoni* SJ strain. Group III contained 12 mice infected percutaneously with 100 cercariae of the *S. mansoni* BH strain 8 weeks prior to being inoculated in the caudal vein with eggs from the *S. mansoni* BH strain. Group IV contained 12 mice infected percutaneously with 100 cercariae of the *S. mansoni* BH strain 8 weeks prior to being inoculated in the caudal vein with eggs from the *S. mansoni* SJ strain.

Two to three animals were used to obtain the mature eggs of the BH strain to be inoculated in the caudal vein of mice. Five to six previously infected animals were used to obtain mature eggs of the SJ strain. The mice in each group were euthanized by cervical dislocation, 1, 8, 15, or 34 days after inoculation with the eggs. On each of these preestablished days, 3 mice from each group were euthanized. The worms were then recovered from the mice in groups III and IV via perfusion of the hepatic portal system [36]. Finally, the recovered worms were separated by gender.

#### 2.3. The Number and Size of the Granulomas in the Liver and the Lungs

In order to count and measure the schistosome granulomas in the liver (Groups III and IV) and in the lungs (Groups I, II, III, and IV) of the euthanized mice, histological slices (5 μm thick) were fixed in Bouin's solution, stained with Masson's trichrome and examined using an optical microscope. The number of granulomas per tissue area (0.984704 mm²) and the extent of the granulomatous response were determined using the techniques described by Magalhães et al. [17]. Only granulomas that contained an *S. mansoni* egg at the center were measured. Measurements were performed using Image-Pro Lite software, (version 4.0) for Windows 95/NT/98.

#### 2.4. Statistical Analysis

The data were analyzed using SAS software for Windows 8.01, 2000 [37].

### 3. Results

Table 1 displays the number of cercariae that effectively penetrated and recovered trematodes from Groups III and IV. There was no significant difference between the number of penetrating cercariae in the two groups (P = 0.4667). The number of trematodes was significantly higher in Group III than in Group IV (P = 0.0012, P = 0.0036, P = 0.0019; male, female, and total number of trematodes, resp.).

#### 3.1. Granuloma Area in the Lung

Table 2, Figures 1, 2, 3, and 4. Table 2 displays the number of pulmonary granulomas found in each of the experimental groups. Figure 1 displays the beginning of the granulomatous reaction one day after inoculation of the BH eggs (Group I) and the SJ eggs (Group II).
Table 1: The table presents the mean number of cercariae and male and female trematodes that were recovered from mice exposed to 100 cercariae of the *S. mansoni* BH strain and inoculated 8 weeks later with eggs from the *S. mansoni* BH (Group III) or SJ (Group IV) strains. The mice were euthanized 1, 8, 15, and 34 days after being inoculated with eggs in the caudal vein.

Figure 1: Formation of a halo cell around mature (a) *S. mansoni* BH (Group I) and (b) SJ (Group II) eggs in the pulmonary parenchyma one day after inoculation of the eggs in the caudal vein of mice.
eggs from the *S. mansoni* BH (Group I) or SJ (Group II) strains and of those that were previously infected with the *S. mansoni* BH strain and then inoculated 8 weeks later with eggs from the *S. mansoni* BH (Group III) or SJ (Group IV) strains. The means with different letters exhibited a significant difference ($\alpha = 0.05$).

The area covered by granulomas differed significantly between the groups, independently of the time since inoculation ($P < 0.0001$). The largest granulomas occurred in Groups III and IV (previously infected with the *S. mansoni* BH strain) and the smallest granulomas were found in Groups I and II (inoculated with eggs from the BH and SJ strains, resp.) (Figure 2). The granulomatous area around the eggs from the BH (Group I) strain was significantly larger than that of the SJ (Group II) strain (Figure 2). The area of the granulomas altered throughout the postinoculation period ($P < 0.0001$), with the smallest granulomas recorded 1 day after inoculation and the largest granulomas recorded after 15 days (Figure 2). Fifteen days after inoculation, the BH eggs had induced a significantly larger granulomatous response than the SJ eggs (Figure 4). The mice previously infected with the *S. mansoni* BH strain (Groups III and IV) exhibited larger granulomas in the lung than the mice in Groups I and II (Figure 2). There was also a significant difference in granuloma size 8 days ($P < 0.0001$) and 34 days ($P < 0.0001$) after inoculation with the eggs (Figure 4). The comparison of mice infected with the *S. mansoni* BH strain and subsequently inoculated with the BH (Group III) or SJ (Group IV) eggs revealed that the granuloma area surrounding BH eggs was significantly larger 8 and 15 days after inoculation (Figure 4).

3.2. The Number of Lung Granulomas (Figures 5 and 6). There were significantly ($P < 0.0001$) more granulomas in the lungs of the mice infected and inoculated with eggs from the BH strain (Group III) (Figure 5). There were no significant differences in the number of granulomas among the other groups (I, II, and IV). Most granulomas were observed 8 and 34 days after inoculation, and the fewest granulomas were found on the first day after inoculation with the eggs. Fifteen days after inoculation, there were no significant differences in the number of granulomas between the four experimental groups. Significantly more granulomas formed on the first day after inoculation in the lungs of previously infected animals (Groups III and IV) than in that of naive mice (Groups I and II). Eight days after inoculation, there were significantly fewer granulomas in the mice from Group IV than in the other groups, whereas no significant difference existed between Groups II and III. Thirty-four days after inoculation, there were significantly more granulomas in Group III than in the other groups (Figure 6).

3.3. The Granulomatous Area in the Liver (Figures 7 to 9). The granulomatous area was assessed in the livers of mice that were previously infected with the *S. mansoni* BH strain (Groups III and IV). No significant difference was found between the two groups in terms of the area covered by hepatic granulomas ($P = 0.7412$) (Figure 7), even when the time after infection was considered (Figure 8). In both
groups, the hepatic granulomatous area increased 8 and 15 days after infection \( (P = 0.0010) \) and then decreased 34 days after inoculation (Figure 9).

3.4. The Number of Granulomas in the Liver (Figures 10 and 11). Significantly more granulomas were observed in the livers of mice from Group III than in the livers of mice from Group IV \( (P < 0.0001) \) (Figure 10). In addition, more granulomas were found 1 and 8 days after inoculation \( (P < 0.0001) \). At these time points, there were significantly more granulomas in mice from Group III than in mice from Group IV (Figure 11).

4. Discussion

The granulomatous response induced by the eggs of \( S. mansoni \) is a protective mechanism initiated by the host organism, although its appearance is also responsible for the disease pathology. The degree of the response by the host organism depends on the stimulating capacity of the parasite and the integrity of the host immune system. According to Lichtenberg [38, 39], the length and size of the granuloma are proportional to the persistence of the egg in the lesion and the ability of the host cells to destroy antigens. The granulomatous reaction plays an important role in protecting host tissues to sequester antigens released by the eggs, while at the same time causing the pathogenesis [39]. The granulomatous response that was induced in the lungs by the BH eggs (Group I and III) was greater than that induced by the SJ eggs (Groups II and IV) (Figure 2). The increased granulomatous response in the lungs was
letters differ significantly ($\alpha = 0.05$).

**Figure 9:** The granulomatous area in the liver of the mice that were previously infected with the *S. mansoni* BH strain and then inoculated 8 weeks later with eggs from the *S. mansoni* BH (Group III) or SJ (Group IV) strains. The mice were euthanized 1, 8, 15, or 34 days following inoculation with the eggs. The means depicted with the same letter do not differ significantly ($\alpha = 0.05$).

**Figure 10:** The number of granulomas in the liver of the mice that were previously infected with the *S. mansoni* BH strain and then inoculated 8 weeks later with eggs from the *S. mansoni* BH (Group III) or SJ (Group IV) strains. The means depicted with different letters differ significantly ($\alpha = 0.05$).

**Figure 11:** The number of granulomas in the liver of the mice that were previously infected with the *S. mansoni* BH strain and then inoculated 8 weeks later with eggs from the *S. mansoni* BH (Group III) or SJ (Group IV) strains. The mice were euthanized 1, 8, 15, or 34 days after the inoculation with the eggs. For each time point, the means depicted with the same letter do not differ significantly ($\alpha = 0.05$).
life cycle [45]. One could hypothesize that the S. mansoni SJ strain is different because B. tenagophila is the natural intermediate host. Geographical strains of S. mansoni have significant pathogenic differences stemming from the degree of organ impairment, which is dictated by the distribution of S. mansoni eggs [9], the number of eggs produced by the parasite [6, 46], and the degree of susceptibility of the snail vector [9, 10, 18].

The increased number of granulomas in the lungs and the liver observed in the animals from Group III (infection with S. mansoni and inoculation with BH eggs) can be attributed to the greater number of eggs resulting from the greater number of worms recovered (Table 1). Granulomatous pulmonary reactions around the eggs were found in mice infected with the BH strain [47]. The granulomas observed in the livers of the mice in Groups III and IV were probably caused by eggs laid by the BH trematodes, since an examination of the livers of the mice in Groups I and II (inoculated with the BH and SJ eggs only) did not reveal the presence of granulomas. The smaller hepatic granulomas found 90 days after infection (34 days after inoculation, Figure 9) resulted from the immunomodulation of the inflammatory response of the eggs during chronic schistosomiasis [48]. The results of the present study showed that granulomas covered a larger area in the lungs of mice that were previously infected with cercariae and subsequently inoculated with eggs from the BH strain. These results indicated that specific granulomatous responses occurred following an infection with the BH and SJ strains of S. mansoni.
